Abstract

This report documents our data analytics project on the King County House Sales dataset, following a subset of the CRISP-DM process. We selected this dataset for a regression task to predict house prices. The analysis covers Business Understanding, Data Understanding, and Data Preparation phases, with emphasis on provenance logging using PROV-O and ontologies. All experiments were conducted in a Jupyter Notebook with automated knowledge graph documentation. The project demonstrates reproducible data mining practices, ethical considerations, and preparation for modeling.

CCS Concepts

- Information systems → Data mining; • Computing methodologies → Machine learning approaches.

Keywords

data analytics, CRISP-DM, house price prediction, regression, feature engineering, provenance

1 Business Understanding

1.1 Data Source and Scenario

The selected dataset is the King County House Sales from Kaggle(<https://www.kaggle.com/datasets/harlfoxem/housesalesprediction>), containing 21,613 instances and 21 attributes on residential property sales in King County, WA, USA (2014–2015). id, date, price (target), bedrooms, bathrooms, sqft living, sqft lot, floors, waterfront (binary), view (ordinal 0-4), condition (ordinal 1-5), grade (ordinal 1-13), sqft above, sqft basement, yrbuilt, yr renovated, zipcode (categorical), lat, long (continuous), sqft living15, sqft lot15. This real-world dataset poses a regression problem to predict house prices, suitable for a business analytics scenario in real estate valuation. In a practical setting, a real estate agency could use this model to provide automated price estimates for clients, optimize listing strategies, and identify market trends in Seattle-area neighborhoods.

1.2 Business Objectives

The primary objective is to develop an accurate house price prediction model to support real estate decision-making, such as advising sellers on competitive pricing, helping buyers assess value, and enabling agencies to forecast market shifts. Secondary objectives include identifying key price drivers (e.g., location, size, quality) to inform investment strategies and reduce manual appraisal time by 50

1. Develop a robust predictive model that accurately predict house sale prices in USA based on property features such as square footage, number of rooms, condition, waterfront to support real-estate pricing decisions.

2. Analyze which property characteristics (e.g. location, grade, renovations, size) have the most influence on sale price to help stakeholders understand market determinants.

1.3 c. Business Success Criteria

1.The developed model is considered successful if it predicts house sale prices with high accuracy, measured by achieving an R^2 score of at least 0.75 and a reasonably low RMSE on a held-out test dataset, ensuring reliable price estimation for decision-making.
2.The analysis successfully shows which property features have the biggest impact on house prices, such as living area, location, grade, and condition. These results are easy to understand, statistically reliable, and consistent with how the real-estate market typically works.

1.4 d. Data Mining Goals

1.Develop and compare supervised regression models(Linear Regression, XGBoost / Gradient Boosting, etc) to predict house sale prices based on structural, locational, and condition-related property features.

2.Perform exploratory and statistical analysis to quantify relationships between input variables and sale price, and to identify the most influential predictors.

3.Apply appropriate data preprocessing techniques, including missing value handling, outlier treatment, feature encoding, and normalization, to ensure model robustness and validity.

Data mining problem type: Supervised learning – Regression

1.5 e. Data Mining Success Criteria

1. Accuracy: The regression model predicts house prices with high accuracy, achieving R^2 0.75 and low RMSE/MAE on the test set.

2.Feature Interpretability: The model clearly identifies the most important property features affecting price (e.g., living area, location, grade), and these are consistent with domain knowledge.

3.Model Robustness: The model performs consistently across training and test sets, with minimal overfitting and stable results under validation.

117 1.6 f. AI Risk Aspects

118 Potential risks include proxy bias from zipcode/lat/long correlating
 119 with socioeconomic or racial demographics (historical redlining in
 120 Seattle). Model could perpetuate inequality if underpredicting in
 121 underrepresented areas. Mitigation: bias auditing with macro/micro
 122 metrics, ethical review, and avoiding direct demographic proxies.
 123

124 2 Data Understanding

125 2.1 a. Attribute Types, Units, Semantics

126 *Dataset Description.* The King County House Sales dataset com-
 127 prises 21 attributes describing residential property transactions in
 128 King County, Washington, spanning the period from May 2014 to
 129 May 2015. The identifier column `id` is a unique long integer serving
 130 solely as a record key and carries no predictive value. The date
 131 attribute captures the sale timestamp in `YYYYMMDDT000000` format,
 132 enabling temporal analysis of market trends.
 133

134 The target variable `price` represents the final sale amount in
 135 US dollars and exhibits strong right-skewness due to the presence
 136 of luxury properties. The `bedrooms` feature denotes the integer
 137 count of sleeping rooms, typically ranging from 1 to 10, with rare
 138 extremes corresponding to studios or large estates. The `bathrooms`
 139 attribute records the number of bathrooms using decimal precision,
 140 where fractional values (e.g., 0.75) indicate partial facilities such as
 141 powder rooms.
 142

143 The variable `sqft_living` measures the interior habitable space
 144 in square feet and emerges as the strongest predictor of `price` due
 145 to its direct relationship with perceived property size. Similarly,
 146 `sqft_lot` quantifies total land area in square feet and displays
 147 extreme right-skewness driven by large rural parcels. The `floors`
 148 attribute indicates the number of building levels, allowing decimal
 149 values to represent split-level designs.
 150

151 The binary feature `waterfront` identifies properties with direct
 152 water access or views, a rare premium characteristic occurring in
 153 fewer than 1% of records. The `view` variable provides an ordinal
 154 rating from 0 (no view) to 4 (excellent view), reflecting scenic quality.
 155 Property condition is captured by the `condition` attribute, rated
 156 on an ordinal scale from 1 (poor) to 5 (very good). Construction
 157 and design quality are assessed using the `grade` feature, based on
 158 the King County grading system with values ranging from 1 to 13,
 159 and this variable is highly predictive of sale price.
 160

161 Geographic information is provided through the categorical
 162 `zipcode` attribute, along with precise latitude and longitude coor-
 163 dinates expressed in decimal degrees, enabling fine-grained spatial
 164 analysis. Finally, `sqft_living15` and `sqft_lot15` represent the
 165 average interior living space and lot size, respectively, of the fifteen
 166 nearest neighboring properties as of 2015, offering contextual
 167 neighborhood-level comparison metrics. All area-related variables
 168 are measured in square feet, while prices are expressed in US dollars.
 169

170 2.2 Data Quality Analysis

171 To assess the quality of the dataset, several key aspects were exam-
 172 ined, including outliers, missing values, and plausibility of feature
 173 values.
 174

175 **2.2.1 Outlier Analysis.** Outliers were detected using the Interquar-
 176 tile Range (IQR) method with a factor of 3, a robust statistical ap-
 177 proach well suited for highly skewed real estate data. The analysis
 178 was applied to the following numerical variables: `price`, `sqft_living`,
 179 `sqft_lot`, `bedrooms`, and `bathrooms`. Values falling outside the in-
 180 terval

$$[Q_1 - 1.5 \cdot IQR, Q_3 + 1.5 \cdot IQR]$$

181 were flagged as potential outliers.
 182

183 The IQR-based analysis identified a substantial number of ex-
 184 treme observations, including approximately 420 properties priced
 185 above 1.6 million US dollars, 74 houses with exceptionally large
 186 living areas, and numerous properties with unusually large lot
 187 sizes. However, these observations do not represent data errors.
 188 Instead, they reflect genuine characteristics of the housing market,
 189 particularly the luxury segment and properties located in rural or
 190 low-density areas. High-end homes and large parcels of land are an
 191 important and meaningful part of the market, especially in regions
 192 such as Medina, Mercer Island, and other similar areas.
 193

194 *Decision.* Outliers were retained in the dataset, as removing them
 195 would introduce bias and reduce the model's ability to accurately
 196 predict high-value properties.
 197

198 During the data preparation stage, the following measures are
 199 applied:
 200

- 201 (1) Logarithmic transformations are applied to `price`, `sqft_living`,
 202 and `sqft_lot` to reduce skewness.
 203
- 204 (2) Tree-based models, such as Random Forest and XGBoost, are
 205 preferred due to their inherent robustness to extreme values.
 206

207 This strategy preserves meaningful market information while
 208 improving model stability and predictive performance.
 209

210 **2.2.2 Missing Values.** The dataset was examined for missing values
 211 across all features. No missing values were detected, and therefore
 212 no imputation was required.
 213

214 **2.2.3 Plausibility Checks.** A comprehensive plausibility check was
 215 conducted for all features to identify invalid or logically inconsis-
 216 tent values. This included verifying the absence of negative or zero
 217 values for key variables such as `price`, living area, lot size, num-
 218 ber of bedrooms, and number of bathrooms. Construction-related
 219 attributes, including `yr_built` and `yr_renovated`, were validated
 220 to ensure chronological consistency and realistic values.
 221

222 Additionally, categorical and ordinal features such as `grade`,
 223 `condition`, `view`, and `waterfront` were checked to confirm that
 224 their values lie within the documented rating scales.
 225

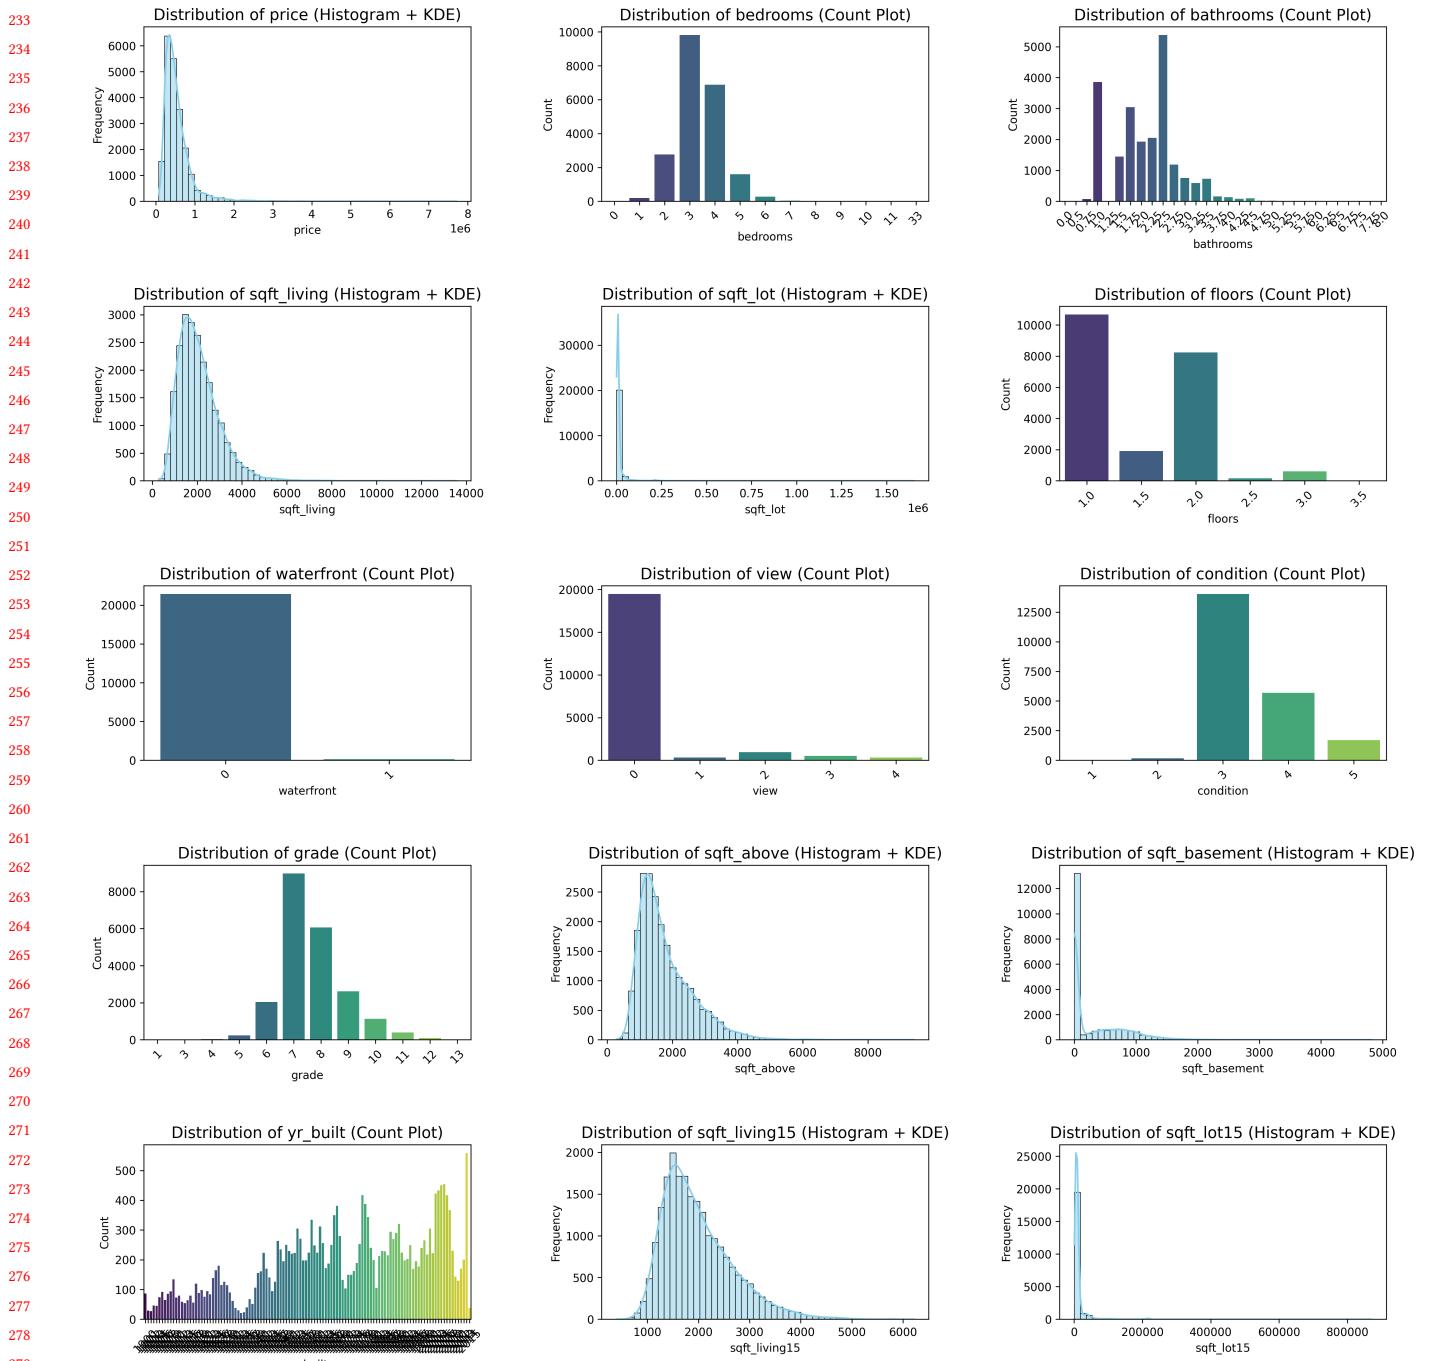

226 An inconsistency was identified in the `bathrooms` feature, where
 227 fractional values (e.g., 2.5) appear. Since the number of bathrooms
 228 is required to be an integer in this analysis, all records containing
 229 non-integer bathroom counts were removed from the dataset.
 230

231 2.3 d. Visual Exploration of Data Properties and 232 Hypotheses

233 Firstly we check the distribution of the data: as below:

234 `graphicx`

235 The price, living space (`sqft_living`), lot size (`sqft_lot`), and related
 236 area features are clearly right-skewed with long tails, which is
 237 expected given the presence of luxury homes and large estates. Most
 238

**Figure 1: Distribution of attributes of data**

houses fall into more typical ranges: bedrooms are concentrated around 3–4, bathrooms around 2.25–2.5, floors are usually 1–2, and grades are mainly centered between 7 and 8, showing that mid-range homes dominate the dataset.

Waterfront properties are very rare, leading to a strong class imbalance. Similarly, most homes have no special view or only an

average one, and condition ratings are mostly fair to good. Basement space is zero for a large portion of the houses, while the year-built feature shows increasing construction activity over time, particularly after 1950. Only a small fraction of homes have been renovated.

349 The features sqft_living15 and sqft_lot15 follow the same skewed
 350 patterns as their corresponding original variables.

351 Below, Exist the corrolation matrix between attributes: Looking
 352 at the Pearson correlation matrix, house price shows strong positive
 353 relationships with several key features. In particular, sqft_living
 354 (0.70), grade (0.67), sqft_above (0.61), and bathrooms (0.53) stand
 355 out, which makes sense—larger homes with better quality and
 356 more amenities tend to be more expensive. There are also moderate
 357 correlations with view (0.40), latitude (0.31)—suggesting that homes
 358 located further north are generally pricier—and waterfront (0.27).
 359 At the same time, many size-related features are highly correlated
 360 with each other, such as sqft_living and sqft_above (0.88) and sqft
 361 living and bathrooms (0.75), indicating a fair amount of redundancy
 362 in the data.

363 In contrast, year_built and year_renovated show little to no mean-
 364 ingful relationship with price. Overall, these results suggest that
 365 living area, grade, bathrooms, and location features are the most
 366 influential predictors of house price, while also highlighting the
 367 need to account for multicollinearity when building models in the
 368 next phase.

369 3. Statistical information:

370 **Table 1: Descriptive Statistics of the King County Housing
 371 Dataset**

Feature	Count	Mean	Min	Std	Skew
id	21613	4.58e9	1.00e6	2.88e9	0.243

sqft_lot15	21613	12768.46	651	27304.18	9.506

398 *Descriptive Statistics Overview.* Table 1 presents descriptive statistics
 399 for all attributes in the King County housing dataset, comprising
 400 21,613 property transactions. All variables contain complete obser-
 401 vations with no missing values. The reported mean, minimum, and
 402 standard deviation capture central tendency and variability, while
 403 skewness quantifies distribution asymmetry.

404 Several key variables, including price, sqft_lot, sqft_living,
 405 and waterfront, exhibit strong positive skewness, reflecting the

407 presence of rare but high-value luxury properties and large land
 408 parcels. In contrast, structural quality indicators such as condition,
 409 grade, and floors display more balanced distributions. Overall,
 410 the statistics highlight substantial heterogeneity in housing char-
 411 acteristics, motivating the use of robust preprocessing techniques
 412 and models capable of handling skewed distributions.

2.4 e. Ethical Sensitivity and Bias Distributions

414 From an ethical and bias perspective, several points stand out in the
 415 data. While there are no direct demographic variables such as race,
 416 income, age, gender, or religion—which helps reduce explicit pri-
 417 vacy and fairness concerns—some geographic features like zipcode,
 418 latitude, and longitude can still act as indirect proxies for socio-
 419 economic status or historically segregated areas in US and Seattle.
 420 This means location-based bias is still something to be aware of.

421 The dataset also contains imbalances across certain groups. For
 422 example, waterfront properties make up only about 0.8 percent of
 423 all homes, making them a very rare category. Similarly, higher view
 424 ratings 3, 4 appear in only around 7 percent of the data, and homes
 425 with very high grades 11, 13 represent a small luxury segment.

426 In addition, key numerical features such as price, sqft_living, and
 427 sqft_lot are heavily right-skewed. Most homes fall into a mid-range,
 428 with a long tail of expensive, high-end properties.

429 These imbalances have important implications for modeling.
 430 Without care, a model may mainly learn patterns from the majority
 431 of average, non-waterfront homes and perform poorly on rare but
 432 important cases. To address this, it's advisable to use evaluation met-
 433 rics that account for imbalance, such as macro-averaged precision,
 434 recall, and F1-score, alongside micro-averaged metrics. Techniques
 435 like stratified sampling or class weighting during training can also
 436 help reduce bias toward the dominant groups.

2.5 f. Potential Risks, Bias Types, and Expert Questions

437 There are several potential risks and sources of bias in this dataset
 438 that are worth noting. 1. First, proxy bias may be present because
 439 variables like zipcode, latitude, and longitude can indirectly reflect
 440 racial, ethnic, or income patterns. In areas such as Seattle and
 441 King County, these geographic features may capture the effects of
 442 historical redlining and ongoing residential segregation. 2. Selection
 443 or sampling bias is another concern. The dataset only includes
 444 officially recorded home sales from 2014–2015, which means certain
 445 types of transactions—such as cash sales, foreclosures, or off-market
 446 deals—may be underrepresented. These transactions are often more
 447 common in specific communities and market segments. 3. There is
 448 also survivorship bias, since the data includes only properties that
 449 were successfully sold. Homes with failed listings or withdrawn
 450 sales are missing, which can skew the picture of market dynamics.
 451 4. Finally, temporal bias exists because the dataset spans a limited
 452 time period. As a result, it does not capture long-term housing
 453 trends or the effects of major events, such as the tech boom, that
 454 may have impacted certain neighborhoods differently over time.

455 To better understand and address these issues, several questions
 456 would require input from domain experts or external data sources:
 457 1. Are specific zipcodes in King County strongly associated with
 458 racial or ethnic composition or household income levels today? 2. Is
 459

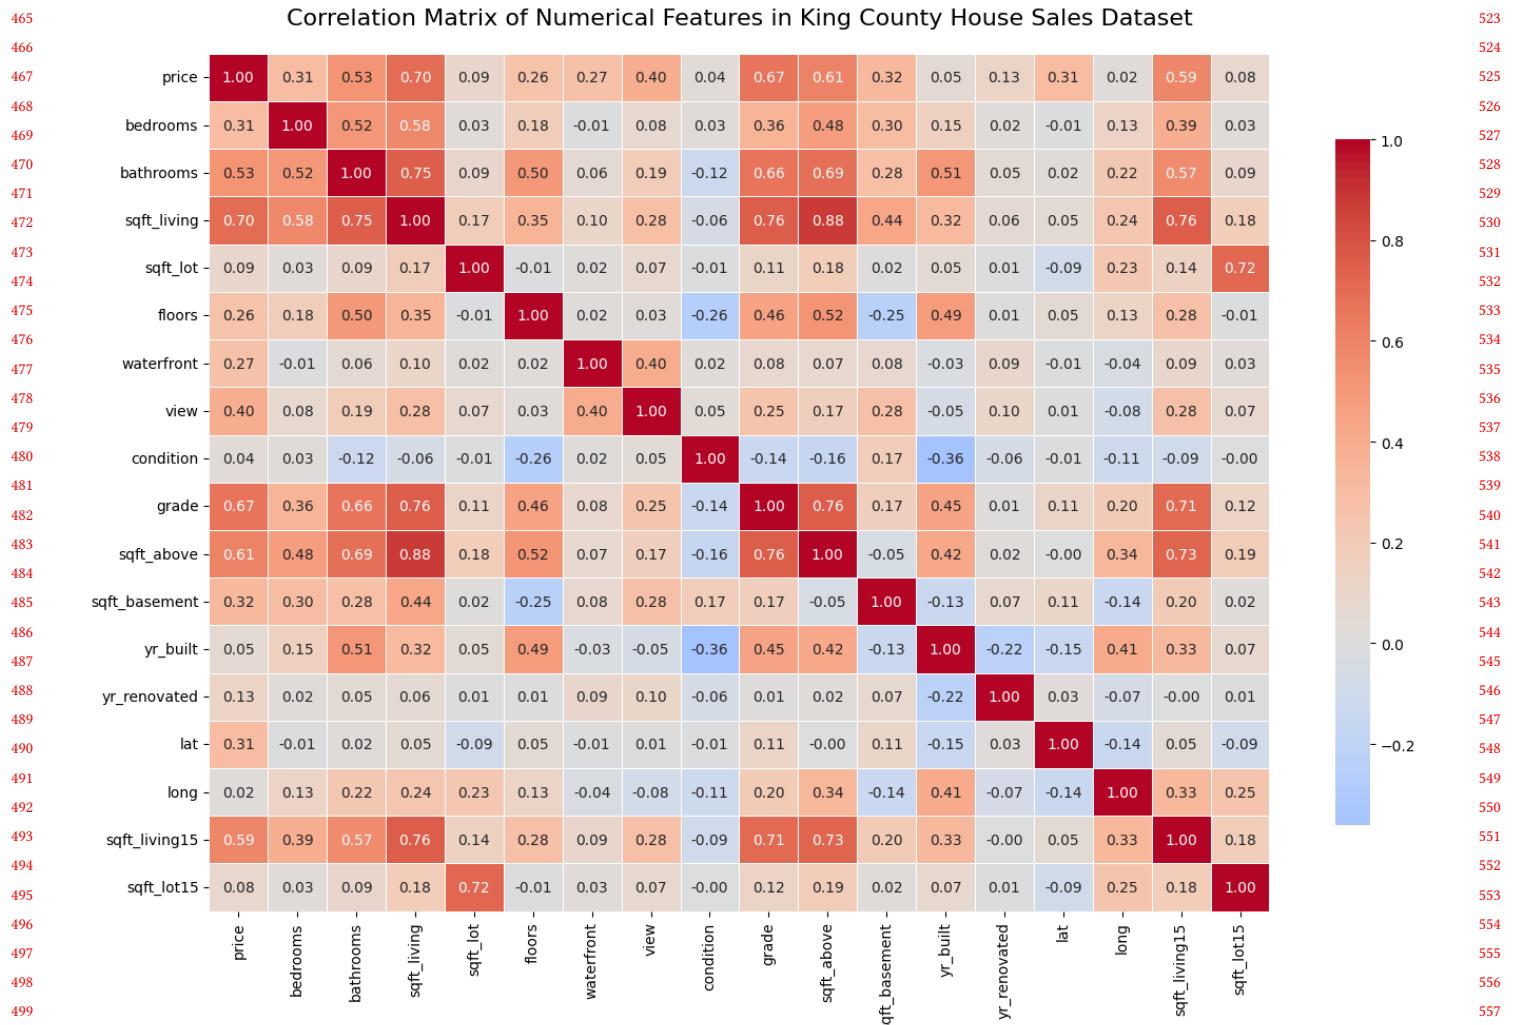

Figure 2: Correlation between attributes

there documented evidence of historical redlining or discriminatory lending practices in neighborhoods covered by this dataset? 3. Does the dataset represent all residential sales?

2.6 g. Required Actions in Data Preparation

Actions planned for Data Preparation phase based on Data Understanding: 1. Feature engineering: - Some of the datapoints should be removed. For example we cannot have bathrooms with number of 2.5 or 3.5. it must be an integer. - We also add some features regarding "total sqft", "bed bath ratio" and "house age". 2. Handling missing values: - There are no missing values; no action needed. 3. Outlier treatment: - Do not remove outliers; instead use robust scaling and tree-based models tolerant to extremes. 4. Encoding and scaling: - Numerical features: StandardScaler or RobustScaler after log transformation. 5. Train/test split: - Stratify by waterfront and binned price to ensure minority classes are represented in both sets.

- ## Data Preparation

1 Pre-processing Actions and Reproducibility

[label=1]

 - (1) We remove records with bathrooms ≤ 0 .
 - In our data, there are only a few such rows, and all of them have positive living area ($\text{sqft living} > 0$) and realistic prices.
 - Therefore, bathrooms = 0 is not plausible for actual houses and most likely represents missing or erroneous data.
 - Removing them improves data quality and has negligible impact on the overall distribution.
 - (2) We keep decimal bathroom values (e.g., 1.25, 1.5, 1.75).
 - Decimal bathrooms are normal in real-estate datasets because they encode partial bathrooms (half/three-quarter baths).
 - (3) We remove the single record with 33 bedrooms.

- 581 • Given its normal living area and price, 33 bedrooms is not
 582 realistic and is very likely a data-entry error (e.g., "3" was
 583 recorded as "33").

585 2. Feature Engineering

586 Performed on the full dataset prior to train/test split to ensure
 587 consistency and prevent data leakage. Three derived attributes
 588 were added:

- 589 [label=1.]
- 590 (1) **Total_sqft**: Consolidated living area (above + basement) –
 591 reduces multicollinearity while preserving interpretability.
- 592 (2) **Bed_bath_ratio**: Luxury/layout proxy – safely computed
 593 with protection against zero-bedroom division.
- 594 (3) **House_age**: Temporal feature encoding age as of 2025 –
 595 captures depreciation and historical construction trends.

597 3. Train/Test Split

599 Performed using GroupShuffleSplit with zipcode as grouping
 600 variable to prevent data leakage across geographic areas.

- 601 • Test size: 20%
- 602 • No overlapping zipcodes between train and test sets (con-
 603 firmed: 0 overlap).
- 604 • Target variable price transformed using np.log1p to ad-
 605 dress strong right-skewness and stabilize variance – stan-
 606 dard practice in real estate price prediction.
- 607 • Original price preserved for final metric reporting in real
 608 dollars.
- 609 • Non-predictive columns (id, date) removed after splitting.

611 This split ensures realistic model evaluation by simulating pre-
 612 diction on unseen neighborhoods.

613 4. Log Transformation

615 Log transformation (np.log1p) applied to strongly right-skewed
 616 area features: sqft_living and sqft_lot.

617 Justification from Data Understanding phase:

- 618 • Both features exhibited high positive skewness (sqft_living
 619 ~ 1.47, sqft_lot ~ 4.12) and long right tails due to large/luxury
 620 properties.
- 621 • Log transformation reduces skewness, stabilizes variance,
 622 and improves linearity – standard best practice in real estate
 623 price modeling.
- 624 • No negative or invalid values present – transformation ap-
 625 plied safely.
- 626 • This aligns with earlier decision to retain all outliers while
 627 mitigating their influence through transformation rather
 628 than removal.

629 **Expected benefits:** Improved performance and stability of lin-
 630 ear models; tree-based models also benefit from reduced extreme
 631 values.

633 3.2 Other Pre-processing Steps Considered but 634 Not Applied

636 During the project, several additional preprocessing steps were
 637 considered but ultimately not used, for specific reasons.

639 1. Outlier removal was initially explored by identifying extreme
 640 values using the IQR method, such as very expensive homes or
 641 properties with exceptionally large lots. However, these data points
 642 represent real and important segments of the U.S. housing market,
 643 particularly luxury homes and large estates. Removing them would
 644 bias the model and limit its ability to make accurate predictions
 645 for high-value properties. Instead of deleting these observations,
 646 a log transformation was applied to reduce their influence while
 647 preserving the full range of the data.

648 2. Binning continuous variables like sqft living, price, or grade
 649 was also considered to potentially improve interpretability, espe-
 650 cially for tree-based models. This approach was not adopted because
 651 keeping features continuous retains more information and allows
 652 models—particularly gradient boosting methods—to learn optimal
 653 split points on their own. Binning would introduce arbitrary cutoffs
 654 and reduce precision without a clear benefit.

655 3. One-hot encoding of zipcode was another option, which would
 656 have created around 70 dummy variables. This was not applied due
 657 to the high dimensionality it would introduce and the increased risk
 658 of overfitting. While target or frequency encoding was briefly con-
 659 sidered, it was ultimately deferred. Tree-based models can handle
 660 zipcode effectively through splits without explicit encoding.

661 4. Additional feature scaling beyond log transformation, such
 662 as applying MinMaxScaler or standardization to all numerical fea-
 663 tures, was also evaluated. This step was not necessary because the
 664 primary models used (Random Forest and XGBoost) are tree-based
 665 and insensitive to feature scale. Scaling was only applied when
 666 comparing against linear baseline models, where it is required.

667 5. Rescaling or normalizing ordinal categorical features, such as
 668 converting grade from a 1,13 scale to a 0, 1 range, was not performed.
 669 The ordinal structure of these variables is naturally preserved and
 670 well utilized by tree-based models, and rescaling offers no practical
 671 advantage.

672 6. Finally, the manual creation of interaction features (for ex-
 673 ample, sqft living * grade) was considered. This was not imple-
 674 mented because tree-based ensemble models inherently capture
 675 complex interactions through their splitting structure. Explicitly
 676 adding interaction terms would increase model complexity without
 677 guaranteeing improved performance.

679 3.3 Options and Potential for Derived Attributes

680 Analysis of options and potential for derived (engineered) attributes
 681 in the US House Sales dataset:

682 1. was renovated (binary: 1 if yr renovated > 0 else 0) and/or years
 683 since renovation - Potential: Moderate – simplifies interpretation
 684 of renovation impact and handles missing values semantically. -
 685 Considered but not applied: Original yr renovated (with 0 for no
 686 renovation) is already interpretable and preserves granularity (exact
 687 year when available). Binary flag adds limited new information.

688 2. distance to downtown (Haversine distance from lat/long to
 689 Seattle center: 47.6062, -122.3321) - Potential: High – location is
 690 a primary price driver; distance could outperform raw lat/long or
 691 zipcode. - Considered but not applied: Adds external dependency
 692 (fixed coordinates); raw lat/long already capture spatial patterns ef-
 693 fectively in tree models via interaction splits. Deferred for potential
 694 future improvement.

697 3. price per sqft = price / sqft living - Potential: Low for prediction
698 task – useful for analysis but causes severe data leakage (price in
699 feature). - Rejected: Invalid for supervised price prediction.

700 4. Binning of continuous features (e.g., grade into low/mid/high)
701 - Potential: Low – reduces granularity. - Not applied: Ordinal nature
702 preserved better as numeric, models benefit from full scale.

703 3.4 d. Options for Additional External Data 704 Sources

705 In This project anything regarding that area can be used in the
706 prediction.

707 1. School quality data - Useful attributes: school ratings, test
708 scores, student-teacher ratio by district or proximity. - Potential:
709 High – major driver for family buyers; often explains price pre-
710 ums in suburban areas.

711 2. Crime statistics (Very Important) - Useful attributes: violent/property
712 crime rates per zipcode or neighborhood. - Potential: Moderate –
713 safety perception affects desirability and price.

714 3. Economic and tax data - Useful attributes: property tax rates,
715 assessed values, unemployment trends. - Potential: Moderate – tax
716 burden impacts affordability and final sale price.

717 4. Transportation and commute data - Useful attributes: com-
718 mute time to downtown Seattle, public transit score, walkability.
719 - Potential: High – proximity to jobs is a key price driver in the
720 region.

721 5. Environmental data - Useful attributes: flood zone status, air
722 quality index, proximity to parks/green spaces. - Potential: Low to
723 moderate – affects insurance costs and lifestyle appeal.
